Preliminary draft — July 19, 2026

Abstract

Keywords: inflation; CPI components; quantile connectedness; broadening; tail dependence.

JEL:

1 Introduction

Inflation targeting has made inflation one of the most closely monitored macroeconomic indicators. When inflation rises sharply, attention shifts from headline inflation alone to the breadth, persistence and propagation of price increases. In 2021 at Jackson Hole, Powell (2021) played down the then recent rise in inflation as narrow and likely temporary, describing it as “largely the product of a relatively narrow group of goods and services that have been directly affected by the pandemic.” By 2022, that assessment had changed: Powell (2022) observed that “high inflation has continued to spread through the economy” and, drawing on the lessons of the 1970s, warned that the anticipation of high inflation can become “entrenched in the economic decisionmaking of households and businesses.”

Powell’s remarks suggest two questions become central for monetary policy when inflation rises. First, are price increases concentrated in a small number of categories? Or have they become broad-based across the household expenditure basket? A relative price shock affecting a limited set of goods can often be looked through; a generalised increase across many categories is harder to dismiss (Bryan & Cecchetti, 1994). Second, has inflation become self-reinforcing through second-round effects in wages and inflation expectations? If higher prices raise wage demands and inflation expectations, and those wages and expectations then feed back into prices, inflation may become more persistent and costly to reduce.

[TODO: [lit review here]]

This paper examines whether high inflation changes the connectedness—the strength of statistical association—among prices, wages and inflation expectations in the United States, and how this connectedness differs across the inflation distribution and between the two major post-war inflation episodes. Connectedness measures, developed to quantify directional spillovers in financial systems (Diebold & Yilmaz, 2012), are well suited to this question because they provide a direct measure of how movements in one series are associated with movements in others. The closest prior contribution to ours is Stenfors et al. (2026), who study connectedness among disaggregated CPI series for the United States, the United Kingdom and Japan since the late 1980s using the time-varying-parameter VAR (TVP-VAR) framework of Antonakakis et al. (2020). We make three contributions relative to that work. The first is *span*: we extend the sample back to the Great Inflation, so that the high inflation of the 1970s and the COVID-era high inflation of 2021–22 can be compared within a common empirical framework. The second is *scope*: alongside the six disaggregated CPI categories we include wages and inflation expectations, which lets us examine wage–price interactions and the inflation–expectations interactions. The third is *methodological*: we replace the connectedness measures derived from the TVP-VAR with the pseudo- R^2 quantile connectedness approach of Shahzad et al. (2026), which better suits the question for two reasons. First, it measures connectedness at different points of the inflation distribution rather than only at the conditional mean or median, so measured connectedness in high-inflation states can differ from that in normal times.¹ Second, it separates *contemporaneous* co-movement from *lagged* propagation, letting us distinguish time series that move together within the period from those linked through delayed pass-through; this is important in distinguishing common shocks from lagged propagation from price series to price series (that is, spiral type behaviour). It is important to note before we proceed that connectedness measures the strength of statistical association, not the strength of identified causal relations; this is sufficient for our purposes.

This paper tests four hypotheses. The first tests whether inflation becomes more broad-based when inflation is high:

H1 (CPI broadening). As inflation rises, connectedness among disaggregated CPI categories increases, particularly in the upper tail of the inflation distribution.

The second asks whether high-inflation states are also associated with stronger wage–price dependence:

H2 (Wage–price interaction). The connectedness between wages and prices is stronger during high-inflation states than during normal-inflation states.

We then compare two major U.S. inflation episodes: the Great Inflation of the 1970s and the COVID-era inflation surge of 2021–22. Much of the conventional understanding of high-inflation dynamics is informed by the 1970s. The pandemic-era surge provides a modern episode, under a

¹A rolling-window TVP-VAR could in principle track connectedness in the two episodes through time, but it still measures connectedness at the centre of the conditional distribution within each window; it cannot isolate behaviour in the tail.

very different monetary policy regime, in which inflation became sufficiently high to revisit those price/wage and inflation dynamics in high inflation environments. The two episodes differed in important respects. The Great Inflation occurred in an economy more dependent on oil and a different monetary policy framework. Further, the COVID-era inflation, differs from the Great Inflation, in that the underlying supply shock affected many prices simultaneously; the pandemic-related supply constraints, in part owing to shipping disruptions, was not just a oil-related phenomenon. These differences suggest that the two episodes may have broadened through different channels. This motivates the third hypothesis:

H3 (Episode mechanism). Price changes during the COVID-era inflation should display strong contemporaneous connectedness, consistent with a large common shock. Price changes during the Great Inflation should be characterised more by lagged propagation across prices.

The differences in monetary policy frameworks between the two periods of high inflation motivate the fourth hypothesis. Specifically, we study if the adoption of inflation targeting and the associated anchoring of inflation expectations alter the connectedness of inflation expectations and inflation:

H4 (Expectations channel). Inflation expectations were a stronger source of inflation propagation during the Great Inflation than during the COVID-era surge.

Our central finding is that the connectedness among prices changes with the level of inflation. Cross-category connectedness among the CPI subcomponents rises roughly threefold from the median to the high-inflation tail (from 11.8 to 35.2 per cent at $\tau = 0.9$), and the increase is accounted for increasingly by the *lagged* rather than the contemporaneous component (23.3 against 11.9 per cent at $\tau = 0.9$). We also find heterogeneity in CPI subcomponent connectedness between the two periods of high inflation. Measured connectedness during the COVID-era inflation surge suggests stronger contemporaneous co-movement during this period, consistent with a common supply shock. Measured connectedness during the Great Inflation suggests more lagged propagation across categories during this period. We find wages and prices are more tightly connected at the top end of the distribution, especially during the Great Inflation. Further, as expected, during the Great Inflation we see strong evidence consistent with a wage price spiral: lagged inflation spills over into wages and lagged inflation spills over into wages. We also find interesting results regarding the connectedness between inflation and inflation expectations. Over the 1983–2019 period where it could be argued inflation expectations were well anchored, expectations net transmit to inflation (net connectedness +29.1 at $\tau = 0.9$). In the high-inflation episodes, however, expectations *follow* realised inflation, consistent with adaptive rather than forward-looking behaviour; this is particularly strong in the Great Inflation.

The remainder of the paper proceeds as follows. Section 2 describes the data; Section 3 sets out the method; and Section 4 reports the tests of the hypotheses.

2 Data

Hypotheses 1 and 3 are to do with the connectedness between CPI subcomponents. Our study uses six monthly CPI subcomponent series; these series collectively cover all of the headline CPI without overlapping. Each is expressed as a month-on-month percentage change and are downloaded from the FRED website. The sample covers February 1967 to May 2026. The six subcomponents are:

- Core goods (excluding food)
- Core services (excluding shelter)
- Shelter
- Food
- Household energy
- Gasoline

There are two exceptions from the standard expenditure-class decomposition: energy is separated into gasoline and household energy services, and core services into shelter and core services excluding shelter. The shelter series is available from FRED, but the core-services-ex-shelter series, we construct as:

$$\% \Delta \text{CoreServ}^{\text{ex-shelter}} = \frac{\% \Delta \text{CoreServ} - w \% \Delta \text{Shelter}}{1 - w}, \quad (1)$$

where $w = 0.60$ is estimated shelter's share of core services.²

We separate shelter from other core services because shelter inflation is driven by distinct dynamics. Specifically, shelter inflation reflects both existing and new rents, and existing rents display nominal rigidity (Genesove, 2003). This rigidity means measured shelter inflation responds to market (new-tenant) rents only with a lag of about four quarters (Adams et al., 2024). This means current changes in the economy might take longer to show up fully in the shelter sub-component of the CPI than other subcomponents.

To test hypotheses 2 and 4, we use three additional series, again from FRED. For the overall Consumer Price Index, we use the Consumer Price Index for All Urban Consumers, All Items, transformed into a month-on-month percentage change to obtain headline inflation.³ Wage growth is measured using the average hourly earnings of production and nonsupervisory employees in the total private sector (AHETPI, dollars per hour, seasonally adjusted), expressed as a month-on-month percentage change. We use this series rather than the broader all employees measure because it is the longest-running monthly earnings series, beginning in 1964, and therefore spans the Great

²[Need to pull the data on CPI shares to justify this decision]

³We omit the overall CPI from the subcomponent system because it is constructed from those very subcomponents, so any connectedness found would in part reflect a mechanical accounting relationship rather than economic co-movement.

Inflation. A long span of data is needed for the comparative analysis of wage and inflation connectedness between the Great Inflation and the COVID Inflation. The broader all-employees series begins only in 2006.

Finally, we use the University of Michigan median expected change in prices over the next twelve months (MICH, percent), available monthly from January 1978. The monthly series therefore misses the 1973–77 period, a key period of the Great Inflation. The Michigan measure is, however, available back to 1960 at a quarterly frequency, so we also run the expectations analysis at a quarterly frequency.

3 Methodology

3.1 Pseudo-quantile R^2 connectedness

Let $\mathbf{y}_t = (y_{1,t}, \dots, y_{K,t})'$ collect the K time series we study. The precise membership of $\mathbf{y}_t$ depends on the hypothesis under study. For hypotheses 1 and 3, $\mathbf{y}_t$ contains the month-on-month percentage change of the six CPI subcomponents. For hypothesis 4 it contains inflation expectations and headline inflation. For hypothesis 2 it contains wage growth and headline inflation.

For each series $y_{k,t}$ in turn within the system $\mathbf{y}_t$, we ask how much of its variation can be attributed to (i) variation of the remaining series in the system at time t , $\mathbf{y}_{-k,t}$, and (ii) the first p lags of all the time series in the whole system, $(\mathbf{y}'_{t-1}, \dots, \mathbf{y}'_{t-p})'$. Channel (i) captures *contemporaneous* connectedness/dependence: the extent to which variables move together within the month (or the quarter), while the second channel (ii) captures *lagged* connectedness/dependence; that is, delayed propagation from one series to another over time. The ability to isolate and distinguish between the two channels is what allows us to separate a common shock from sequential pass-through.

A natural starting point to decompose the contribution of the two channels is the goodness of fit of a regression as measured by the R^2 . Consider the following regression containing inflation (π) and inflation expectations (π^e):

$$\pi_t = \alpha_0 + \alpha_1 \pi_t^e + \sum_{i=1}^p \beta_i \pi_{t-i}^e + \sum_{i=1}^p \gamma_i \pi_{t-i} + \epsilon_t.$$

The R^2 tells us how well collectively inflation is correlated with inflation expectations in time t , lagged inflation expectations and lagged inflation. A natural decomposition is therefore to start with the amount of the total variation in inflation explained by the regression as measured by R^2 . And then decompose it into the amount explained by the contemporaneous term ($\alpha_1 \pi_t^e$) and the amount of variation explained by the lagged terms. The issue with this decomposition is the lags of inflation expectations are correlated with the contemporaneous value of inflation expectations, so the regression R^2 cannot be partitioned unambiguously into the portions that reflect the lagged and the contemporaneous contributions respectively. This problem is exacerbated when you move

to more than two variables (like the six individual subcomponents of the CPI) and therefore have contemporaneous and lagged values of two or more independent variables in the regression; if these variables are correlated, the partitioning of the R^2 becomes even more fraught.

Genizi (1993) proposes an order-invariant decomposition of the regression R^2 that distributes it across correlated regressors through the symmetric (eigenvalue) square root of their correlation matrix. Let $\mathbf{R}_{xx}$ denote the correlation matrix of the regressors, with eigendecomposition $\mathbf{R}_{xx} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}'$, where $\mathbf{V}$ holds the eigenvectors and $\mathbf{\Lambda}$ the eigenvalues. Defining the symmetric square root $\mathbf{C}$, the vector of decomposed R^2 shares is

$$\mathbf{R}_{xx} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}' = \mathbf{C}\mathbf{C}', \quad (2)$$

$$\mathbf{C} = \mathbf{V}\mathbf{\Lambda}^{1/2}\mathbf{V}', \quad (3)$$

$$\mathbf{R}^{2,d} = [\mathbf{C}^2(\mathbf{C}^{-1}\mathbf{r}_{yx})^2]', \quad (4)$$

where $\mathbf{r}_{yx}$ is the vector of correlations between the dependent variable and each regressor. Each entry of $\mathbf{R}^{2,d}$ is the share of the regression R^2 owed uniquely to a single regressor, net of the correlation it shares with the others; the entries are non-negative and sum to the regression R^2 .

Using the above decomposition with Pearson correlations as inputs, Balli et al. (2023) show how contemporaneous and lagged connectedness can be quantified at the centre of the distribution. Because, however, our interest is in how dependence behaves when inflation is high, we use the adaptation of Shahzad et al. (2026), which replaces the Pearson correlations with the quantile correlations of Choi and Shin (2022); this allows contemporaneous and lagged connectedness to be measured at any chosen quantile τ .

The quantile correlation of Choi and Shin (2022) between two variables x_1 and x_2 at quantile τ is

$$r_{1,2,\tau} = r_{2,1,\tau} = \text{sign}(b_{x_1|x_2}(\tau)) \sqrt{b_{x_1|x_2}(\tau) b_{x_2|x_1}(\tau)}, \quad 0 < \tau < 1, \quad (5)$$

where $b_{x_1|x_2}(\tau)$ and $b_{x_2|x_1}(\tau)$ are the slope coefficients from the τ -quantile regressions of x_1 on x_2 and of x_2 on x_1 , respectively. At $\tau = 0.5$ this is a median-based analogue of the Pearson correlation.

The specifics of the Shahzad et al. (2026) measure are as follows. The quantile correlation of Choi and Shin (2022) between two variables, $r_{1,2,\tau}$, is substituted for $\mathbf{R}_{xx}$ and $\mathbf{r}_{yx}$ in equations 2 and 4. For each time series in turn, equation 4 then returns a vector $\mathbf{R}_\tau^{2,d}$ that allocates the regression's overall pseudo- R^2 across its regressors at that τ .⁴ The first $K - 1$ entries record the contemporaneous contributions of the other series; the remaining entries record the lagged contributions of all series in the system.⁵

For a system of K variables, applying the decomposition with the quantile correlation for each

⁴Quantile regressions do *not* have an R^2 in the conventional (least-squares) sense, hence the term “pseudo”.

⁵A quantile-correlation matrix estimated from a finite sample need not be positive semi-definite; a difficulty that becomes more pronounced in the tails ($\tau = 0.9$ in our data) and in short rolling windows. As per Shahzad et al. (2026), we apply the Schäfer and Strimmer (2005) shrinkage procedure to keep the quantile-correlation matrix positive semi-definite.

of the K equations in that system and stacking the results yields the connectedness matrix

$$\mathbf{R}_\tau^{2,d} = \begin{bmatrix} \mathbf{R}_{\tau,1}^{2,d} \\ \vdots \\ \mathbf{R}_{\tau,K}^{2,d} \end{bmatrix} = [\mathbf{R}_{lag=0,\tau}^{2,d} \mid \mathbf{R}_{lag=1,\tau}^{2,d} \mid \cdots \mid \mathbf{R}_{lag=p,\tau}^{2,d}], \quad (6)$$

in which row k indexes the dependent variable.⁶

The total connectedness index at quantile τ , TCI_τ , is the average across the K series of the off-diagonal elements of $\mathbf{R}_\tau^{2,d}$ shares and splits into a contemporaneous and a lagged component:

$$\text{TCI}_\tau = \text{TCI}_\tau^C + \text{TCI}_\tau^L, \quad (7)$$

with

$$\text{TCI}_\tau^C = \frac{1}{K} \sum_{k=1}^K \sum_{j \neq k} \mathbf{R}_{lag=0,\tau,k,j'}^{2,d} \quad \text{TCI}_\tau^L = \frac{1}{K} \sum_{k=1}^K \sum_{j \neq k} \sum_{l=1}^p \mathbf{R}_{lag=l,\tau,k,j'}^{2,d} \quad (8)$$

where $\mathbf{R}_{lag=l,\tau,k,j}^{2,d}$ is the share of series k 's variation contributed by series j at lag l .

Directional measures in a similar spirit to those put forward by Diebold and Yilmaz (2012) can also be calculated. The total connectedness *received* by series k (its FROM measure) sums the shares contributed by all *other* series, at every lag, along row k of $\mathbf{R}_\tau^{2,d}$:

$$\text{FROM}_{k,\tau} = \sum_{j \neq k} \mathbf{R}_{lag=0,\tau,k,j}^{2,d} + \sum_{j \neq k} \sum_{l=1}^p \mathbf{R}_{lag=l,\tau,k,j}^{2,d}. \quad (9)$$

The total connectedness *transmitted* by series k to the other series (its TO measure) sums the shares it contributes, at every lag, down the column corresponding to series k in each lag block of $\mathbf{R}_\tau^{2,d}$:

$$\text{TO}_{k,\tau} = \sum_{j \neq k} \mathbf{R}_{lag=0,\tau,j,k}^{2,d} + \sum_{j \neq k} \sum_{l=1}^p \mathbf{R}_{lag=l,\tau,j,k}^{2,d}. \quad (10)$$

The net directional connectedness of series k ,

$$\text{NET}_{k,\tau} = \text{TO}_{k,\tau} - \text{FROM}_{k,\tau}, \quad (11)$$

is positive when k is, on balance, a transmitter of connectedness and negative when it is a net receiver.

We prefer this measure of quantile connectedness to other approaches to quantile connectedness,

⁶So that the equations align, the k th position of $\mathbf{R}_{\tau,k}^{2,d}$ is set to zero, since $y_{k,t}$ is not regressed on its own contemporaneous value.

such as that of Ando et al. (2022). Those measures propagate the non-zero-mean residuals from quantile regressions through a generalised forecast-error variance decomposition that treats them as zero-mean shocks. As Shahzad et al. (2026) show, this inflates measured connectedness in both tails.

4 Results

4.1 H1: inflation broadens in the high tail

Our first hypothesis is **H1 (CPI broadening)**: *as inflation rises, connectedness among disaggregated CPI categories increases, particularly in the upper tail of the inflation distribution*. Figure 1 reports the overall connectedness at different levels of τ over our whole sample period on a monthly frequency (the black line). Further, the figure shows the decomposition into contemporaneous (the blue line) and lagged (the red line) connectedness. Overall connectedness rises about threefold from the median to the high tail (from 11.8 to 35.2 at monthly frequency); both the contemporaneous and lagged components increase, but slightly more of the rise comes from the lagged component (23.3 vs 11.9 at $\tau = 0.9$).

Note, however, these estimates of connectedness are based off estimating the system with two lags; longer lag lengths are not possible as there is a risk the quartile-correlation matrix is no longer positive semi definite.⁷ This means the connectedness is being measured over a relatively short span of time: two months. We also run the system on a quarterly frequency. The idea being that two lags now capture a longer span of time i.e. two quarters/six months; this allows more time for prices to spillover into other prices. Table 1 reports connectedness measured at a monthly (Panel A) and quarterly (Panel B) frequency for selected quartiles. The table indicates that key conclusions from the monthly analysis hold at a quarterly frequency: high-inflation states are characterised by increased connectedness and, in particular, increased lagged connectedness. Based on this evidence, we conclude hypothesis one is strongly supported.

[Figure 1 about here.]

[Table 1 about here.]

4.2 H2: Wages and inflation

The second hypothesis states that connectedness between wages and prices is stronger during high-inflation states than during normal-inflation states. Panel A of Table 2 shows that the connectedness between wages and the overall CPI inflation rises with the quantile, and that at higher quantiles the

⁷As we use shrinkage procedures (Schäfer & Strimmer, 2005) to keep the matrix positive semi definite, the real issue, therefore, is the shrinkage required to keep it positive semi-definite grows large enough to distort the resulting connectedness estimates.

lagged inflation–wage association strengthens; this pattern holds at quarterly frequency (Panel B). ... This provides strong support for Hypothesis 2. Further, we note that measured connectedness is stronger in both directions when estimated on quarterly data; this may indicate that nominal rigidities are less binding across two quarters than across two months, so that price and wage changes become more closely associated.⁸

To understand how wage and inflation dynamics changed during the two inflation episodes in our sample (the Great Inflation and the COVID inflation), we conduct a ‘one in/ one out’ exercise; see Panel C. In the Great-Inflation-inclusive subperiod (1964–2019): wage–price connectedness is much stronger and the spillovers are in both directions; this is consistent with a reinforcing wage and price spiral. For example, at $\tau = 0.9$, the 1964–2019 sample has spillovers from inflation to wages at 15.5 and 14.9 in the opposite direction i.e. roughly even. Examining the results from the sample including COVID, but excluding the Great Inflation (1983–2026), we make two observations. The first is the spillovers are relatively stronger from inflation to wages (3.0) than in the other direction (1.3).

The second, and more important, observation is the level of connectedness is much lower if the Great Inflation is excluded from the sample period. In part, this reflects that the level of inflation was much higher during the Great Inflation, so a given τ is associated with higher inflation in the 1964–2019 sample than in the 1983–2019 sample. It may also reflect that with better-anchored inflation expectations, wage price spirals are less likely. Panel D provides evidence that the stronger wage–price spiral in the Great-Inflation-inclusive period is not merely an artefact of the two subperiods sitting at different inflation levels for a given τ . In the post-1983 sample, $\tau = 0.7$ and $\tau = 0.9$ correspond to month-on-month CPI inflation of about 4 and 6.3 per cent annualised respectively; these same levels sit at $\tau = 0.618$ and $\tau = 0.785$ in the 1964–2019 distribution of annualised inflation. Panel D therefore evaluates the 1964–2019 connectedness at these latter quantiles, so that connectedness is compared with the post-1983 sample at a common inflation level rather than a common quantile. Even on this like-for-like inflation level basis, connectedness between CPI inflation and wage growth remains far higher in the 1964–2019 sample (total connectedness of 14.7 and 22.1, against 1.8 and 3.6 post-1983), consistent with a stronger wage–price spiral during the era that includes the Great Inflation

[Table 2 about here.]

4.3 H3: The two high inflation episodes were different in terms of how price changes propagated at a CPI subcomponent level

Table 3 reports how connectedness among the CPI subcomponents changes when each high inflation episode is added to the 1983–2019 sample, at $\tau = 0.7$ and $\tau = 0.9$. That is, we estimate the

⁸Some of the higher quarterly connectedness may also come about because of temporal aggregation which averages out high-frequency idiosyncratic movements and so tends to raise measured co-movement. We therefore read the quarterly result as suggestive.

model with the Great Inflation included (but the COVID inflation dropped), and then with COVID inflation included (but the Great Inflation dropped), in each case subtracting the 1983–2019 baseline. Adding the Great Inflation raises both contemporaneous and lagged connectedness by more than adding COVID inflation does, consistent with its higher inflation level. More telling than the size of the increase, however, is its composition: the two episodes broaden inflation through different channels. The Great Inflation increase comes mainly through the *lagged* component, at both quantiles, whereas the COVID inflation increase is entirely *contemporaneous* and is visible only at $\tau = 0.9$; its lagged component is in fact negative at both quantiles. The contemporaneous nature of the COVID inflation connectedness increase is consistent with a common shock, namely pandemic supply constraints and shipping disruption, driving inflation across categories simultaneously. The predominantly lagged Great-Inflation increase is consistent with inflation propagating across categories over time. Both patterns support H3.⁹

In the previous paragraph we noted that part of the larger increase in connectedness when the Great Inflation is added to the sample, relative to when COVID is added, reflects the fact that a given τ corresponds to higher inflation in the Great Inflation. Panels B and C of Table 3 address this by matching on the inflation *level* rather than the quantile, in two ways. During the COVID episode, annualised month-on-month inflation at $\tau = 0.9$ was 8.7 per cent; Panel B re-estimates the change in connectedness at the τ that corresponds to this level within each episode: $\tau = 0.69$ when the Great Inflation is included, and $\tau = 0.9$ when COVID is included. Panel C instead fixes a common level of 5 per cent annualised, finds the corresponding quantile in each episode, and re-estimates. The conclusion is the same throughout: even at the same inflation level, the Great Inflation’s marginal increase in connectedness substantially exceeds COVID’s (for example, +12.2 against +1.1 at the common 8.7 per cent level, and +5.6 against +0.7 at 5 per cent) and is predominantly lagged, whereas COVID’s much smaller increase comes through contemporaneous connectedness.

[Table 3 about here.]

4.4 H4: Inflation expectations and headline inflation

Table 4 reports the directional connectedness of inflation expectations and headline inflation, together with the net directional connectedness of expectations ($\text{NET} = \text{TO} - \text{FROM}$; positive values mean expectations lead, negative that they follow).¹⁰ Note this is carried out on a quarterly fre-

⁹We do not report quarterly aggregated analysis for these hypothesis as adding the COVID window contributes only 26 quarters, so the far tail of the quarterly distribution rests on a handful of observations.

¹⁰Inflation here is quarter-on-quarter growth in the CPI. There is an argument we should instead use annual (four-quarter) growth, to match the one-year horizon of the inflation expectations survey question. At a quarterly frequency, however, overlapping four-quarter changes share three of their four quarters of CPI data with the adjacent observations, mechanically inducing a moving-average component in the series; this smoothness inflates measured *lagged* connectedness in both directions. Re-running the table with four-quarter inflation leaves the net lead/follow pattern across samples intact, though the size of the Great-Inflation lagged asymmetry is sensitive to the choice; these results are available from the authors on request.

quency so we can study a sample that includes the Great Inflation; monthly expectations data only become available in January 1978 (a monthly version of this analysis, on the post-1978 sample, is reported in Appendix C and is consistent with the quarterly results). Pooled over the full sample, inflation expectations are net transmitters in the upper tail. Taking $\tau = 0.9$ as an example, contemporaneous plus lagged transmission from inflation to inflation expectations is $(19.5+33.6)$ 53.1; it is $(26.2+37.3)$ 63.5 in the other direction. If one excludes the two large inflation episodes in our sample and focuses on the 1983–2019 period, the stronger connectedness from inflation expectations to inflation (rather than vice versa) is still evident. We then add the two high-inflation episodes back into this core 1983–2019 sample, one at a time. The 1960–2019 and 1970–2019 samples do this for the Great Inflation, and both show considerably higher lagged connectedness from inflation to expectations than the 1983–2019 sample (36.6 and 40.7 at $\tau = 0.9$, against 11.9). The COVID inflation is added in the 1983–2026 and 1993–2026 samples. In these samples the connectedness is strengthened in the other direction: lagged expectations are more strongly connected with inflation than in the 1983–2019 sample.

Again, we recognise that a given τ corresponds to a different rate of inflation in each sample, so the final row of each block (marked ‡) reports connectedness at the quantile whose quarter-on-quarter CPI inflation equals 5 per cent annualised within that sample, so that connectedness is compared at a common inflation level rather than a common quantile. Our key result still holds: when the Great Inflation is in the sample, lagged connectedness from inflation to expectations is stronger (for example 30.6 over 1960–2019, against 20.5 over 1983–2019). This is consistent with adaptive inflation expectations during that period, with recent inflation spilling over into expectations. When the COVID inflation is added instead, this adaptive channel does not strengthen; the lagged expectations-to-inflation direction remains the dominant one.

[Table 4 about here.]

A Connectedness matrices

Tables 5–10 report the full pairwise connectedness structure among the six CPI subcomponents at $\tau = 0.9$ ($n_{\text{lag}} = 2$), separately for the contemporaneous and lagged blocks, for the full sample and the two subperiods (1967–1982 and 1983–2026). In each matrix, cell (i, j) is the share of row i 's variation attributed to column j ; FROM is the row sum (received), TO the column sum (transmitted), and $\text{NET} = \text{TO} - \text{FROM}$. The contemporaneous block is close to symmetric (small NET), whereas the lagged block carries the directional structure — shelter and core services are the net lagged transmitters. Gasoline is weakly connected to the other categories: its variation is dominated by energy-market (crude-oil) movements that lie outside the CPI system, so it sits at the periphery of the network.

[Table 5 about here.]

[Table 6 about here.]

[Table 7 about here.]

[Table 8 about here.]

[Table 9 about here.]

[Table 10 about here.]

B Goods-to-services sequencing: a lag-window illustration

A frequently cited feature of the 2021–22 surge is that goods inflation led services inflation. Our framework recovers this, but only once the measurement window is long enough — which is itself instructive about connectedness measurement. Table 11 reports, on the post-1983 sample at $\tau = 0.9$, the net lagged connectedness from core goods to core services. Under the monthly two-lag dependence (Genizi) metric the sign is slightly negative (-1.2): a two-month window is too short to span a multi-month goods-then-services sequence. The LASSO predictive metric, which admits longer lags, recovers the ordering ($+1.3$ at two lags, $+5.9$ at six, where core goods becomes a net transmitter). Table 12 confirms it at quarterly frequency, where a two-lag block spans six months: the lagged goods→services term then exceeds the reverse at $\tau = 0.5$ (9.9 vs 4.4) and $\tau = 0.7$ (11.2 vs 7.1). The point is methodological — lag-window length materially affects what connectedness detects, which motivates the quarterly analysis used elsewhere — rather than a new fact about the episode.

[Table 11 about here.]

[Table 12 about here.]

C Monthly robustness for the inflation–expectations system

Table 4 in the main text is estimated at a quarterly frequency, because only the quarterly Michigan survey reaches back before the Great Inflation. Table 13 reports the monthly analogue on the post-1978 sample, pairing the monthly Michigan series with month-on-month CPI inflation. The qualitative pattern matches the quarterly results: expectations lead in the calm 1983–2019 core (NET $+24.1$ at $\tau = 0.9$) and follow during COVID, and in the portion of the Great Inflation the monthly survey covers (1978–82) the lagged terms dominate the contemporaneous ones. The 1978–82 sample contains only 60 months, so its estimates — particularly at $\tau = 0.9$ — carry wide uncertainty and should be read as corroborative rather than free-standing evidence.

[Table 13 about here.]

D One-in/one-out episode marginals for the expectations system

The episode rows of Table 4 are estimated on each episode in isolation. For comparability with the six-CPI episode analysis (Table 3), Table 14 reports the same one-in/one-out construction for the inflation–expectations system: each episode’s marginal contribution to total connectedness relative to the calm 1983–2019 core. The Great-Inflation marginal is large and overwhelmingly lagged at both quantiles (83 and 105 per cent lagged shares at $\tau = 0.7$ and 0.9), consistent with the adaptive channel operating through recent realised inflation. COVID’s marginal is essentially zero at $\tau = 0.7$; its positive $\tau = 0.9$ marginal rests on the 26 quarters the window adds and warrants the same caution as the quarterly episode results in the main text.

Table 1 H1 — Inflation broadens into the high tail

<i>Panel A. Monthly total connectedness by quantile</i>			
τ	Overall	Contemporaneous	Lagged
0.1	5.5	2.8	2.8
0.3	7.5	2.7	4.8
0.5	11.8	4.7	7.2
0.7	19.7	7.1	12.6
0.9	35.2	11.9	23.3

<i>Panel B. Quarterly total connectedness by quantile</i>			
τ	Overall	Contemporaneous	Lagged
0.1	16.9	8.3	8.6
0.3	17.6	6.8	10.8
0.5	27.7	10.7	17.1
0.7	55.7	21.6	34.1
0.9	86.8	33.8	52.9

Notes: Pseudo-quantile R^2 (Genizi/nearPD) connectedness (%) among the six CPI subcomponents; Overall = Contemporaneous + Lagged, $n_{\text{lag}} = 2$. Panel A is monthly 1967–2026 (broadening ratio $\text{TCI}(0.9)/\text{TCI}(0.5) = 2.98\times$); Panel B quarterly 1967Q2–2026Q2 (ratio $3.13\times$). Both frequencies show the tail rise, increasingly driven by the lagged component. Point estimates; bootstrap confidence intervals for the six-CPI system are to be added.

Table 2 H2 — Wage–price connectedness is stronger when inflation is high

<i>Panel A. Two-variable wage–CPI system (monthly, full sample), by quantile</i>			
	$\tau = 0.5$	$\tau = 0.7$	$\tau = 0.9$
Wage–CPI total connectedness (TCI)	10.8	16.6	21.6
lagged Wages→CPI	5.0	7.7	11.5
lagged CPI→Wages	6.2	9.2	16.1
<i>Panel B. Quarterly (full sample), by quantile</i>			
	$\tau = 0.5$	$\tau = 0.7$	$\tau = 0.9$
Wage–CPI total connectedness (TCI)	25.7	32.6	53.4
lagged Wages→CPI	14.6	19.3	35.1
lagged CPI→Wages	13.0	18.5	23.8
<i>Panel C. By subperiod (monthly), by quantile</i>			
	$\tau = 0.5$	$\tau = 0.7$	$\tau = 0.9$
<i>1964–2019 (with Great Inflation)</i>			
Wage–CPI total connectedness (TCI)	13.3	18.4	25.2
lagged Wages→CPI	6.0	9.1	15.5
lagged CPI→Wages	5.9	9.0	14.9
<i>1983–2026 (post-Great-Inflation)</i>			
Wage–CPI total connectedness (TCI)	1.2	1.8	3.6
lagged Wages→CPI	0.2	0.2	1.3
lagged CPI→Wages	0.9	1.7	3.0
<i>Panel D. 1964–2019 (with Great Inflation), level-matched τ (monthly)</i>			
	Matched to $\tau=0.7$	Matched to $\tau=0.9$	
Wage–CPI total connectedness (TCI)	14.7	22.1	
lagged Wages→CPI	7.2	13.2	
lagged CPI→Wages	7.4	13.3	

Notes: Two-variable system of wage growth (AHETPI) and overall CPI (CPI-AUCSL); pseudo-quantile R^2 connectedness (%), Genizi estimator, $n_{\text{lag}} = 2$. Wage–price connectedness rises sharply into the high-inflation tail at all frequencies (Panels A–B), and is far stronger in the Great-Inflation-inclusive subperiod (1964–2019) than post-1983 (Panel C). In the high tail the lagged components dominate. Quarterly ($n_{\text{lag}} = 2$) spans a six-month horizon. Panel D addresses the fact that comparing the two subperiods at the same τ compares different inflation *levels*: it reports the 1964–2019 connectedness at the quantiles ($\tau = 0.62$ and 0.78) whose month-on-month CPI-inflation level matches that of the post-1983 sample at $\tau = 0.7$ and $\tau = 0.9$ (about 4.0 and 6.3 per cent annualised). Even level-matched, 1964–2019 connectedness (14.7 and 22.1) remains far above the post-1983 values in Panel C (1.8 and 3.6), so the gap is not a level artefact; the level-matched spillovers also stay roughly symmetric, the balanced feedback characteristic of a spiral.

Table 3 H3 — COVID broadened contemporaneously; the Great Inflation through lagged propagation

<i>Panel A. Marginal $\Delta TCI(\tau)$ vs. the 1983–2019 core, same τ</i>			
Episode	Δ Overall	Δ Contemp.	Δ Lagged
$\tau = 0.7$			
GreatInflation (1967-82)	+12.3	+4.4	+7.9
COVID (2020-26)	-0.1	+0.0	-0.2
$\tau = 0.9$			
GreatInflation (1967-82)	+14.3	+5.0	+9.3
COVID (2020-26)	+1.1	+1.9	-0.8
<i>Panel B. Level-matched to COVID $\tau = 0.9$ (8.7% annualised)</i>			
Episode	Δ Overall	Δ Contemp.	Δ Lagged
Great Inflation ($\tau = 0.69$)	+12.2	+4.4	+7.9
COVID ($\tau = 0.90$)	+1.1	+1.9	-0.8
<i>Panel C. Level-matched to a common 5% annualised threshold</i>			
Episode	Δ Overall	Δ Contemp.	Δ Lagged
Great Inflation ($\tau = 0.35$)	+5.6	+1.9	+3.6
COVID ($\tau = 0.64$)	+0.7	+0.6	+0.1

Notes: Each episode’s marginal contribution to monthly connectedness relative to the calm 1983–2019 core (nested subtraction), split into contemporaneous and lagged; six-CPI system, $n_{\text{lag}} = 2$. Panel A compares the episodes at the same quantile $\tau \in \{0.7, 0.9\}$. Because a given τ corresponds to a higher inflation level in the Great Inflation, Panels B and C instead match on the inflation *level*: each episode is evaluated at the τ whose annualised month-on-month CPI inflation equals a common reference — the COVID $\tau = 0.9$ level of 8.7 per cent in Panel B, and 5 per cent in Panel C. Throughout, the Great Inflation broadened mainly through the *lagged* (propagation) channel, whereas COVID broadened contemporaneously (its lagged marginal is negative). The level-matched panels show the Great Inflation’s larger broadening is not merely a level artefact. [†] The implied τ falls outside $[0.05, 0.95]$ (the reference level sits beyond that episode’s inflation distribution) and is clamped to the boundary.

Table 4 H4 — Contemporaneous and lagged connectedness between inflation and expectations

Notes: Pseudo-quantile R^2 connectedness (%) among the six CPI subcomponents at $\tau = 0.9$, $n_{\text{lag}} = 2$. Cell (i, j) is the share of row i 's variation attributed to column j . FROM = row sum (received); TO = column sum (transmitted); NET = TO–FROM (> 0 net transmitter). Diagonal (own) terms are excluded from FROM/TO (and shown for the lagged block as the own-lag/persistence term).

Table 11 Goods-to-services sequencing under alternative metrics and lag lengths

Metric	Goods→services (lagged, net)	Core goods NET
Genizi dependence ($n_{\text{lag}}=2$)	-1.2	-3.4
LASSO predictive ($n_{\text{lag}}=2$)	+1.3	+3.4
LASSO predictive ($n_{\text{lag}}=6$)	+5.9	+12.9

Notes: “Goods→services (lagged, net)” is lagged connectedness from core goods to core services (shelter + core services ex-shelter) minus the reverse, at $\tau = 0.9$ on the ex-Great-Inflation sample (1983–2026); > 0 means goods lead. The two-lag Genizi dependence metric cannot see a multi-month sequence and tilts negative; the LASSO predictive metric confirms the sequencing, increasingly at longer lags. Predictive ordering, not identified causation.

Table 12 Goods-to-services: contemporaneous and lagged connectedness (quarterly)

τ	Goods $\rightarrow$ Services		Services $\rightarrow$ Goods	
	Contemp.	Lagged	Contemp.	Lagged
0.5	3.3	9.9	3.4	4.4
0.7	8.5	11.2	8.7	7.1
0.9	13.1	18.4	15.2	18.3

Notes: Pairwise pseudo-quantile R^2 connectedness (%) between core goods and core services (shelter + core services ex-shelter) on the ex-Great-Inflation quarterly sample (1983Q1–2026Q2, 174 quarters), $n_{\text{lag}} = 2$ (a six-month lag horizon). “Goods $\rightarrow$ Services” is the share of services’ variation explained by goods, split into contemporaneous and lagged; “Services $\rightarrow$ Goods” is the reverse. The *lagged* Goods $\rightarrow$ Services term is the “goods lead” propagation channel; it exceeds the lagged Services $\rightarrow$ Goods term at every quantile (by 4.0 at $\tau = 0.7$), consistent with goods leading services. Six months is the horizon the monthly two-lag metric could not span. Dependence, not identified causation.

	0.7	4.6	8.7	5.4	3.6	-4.3
	0.9	3.2	5.5	3.4	4.2	-1.1

Notes: Monthly analogue of Table 4: pairwise pseudo-quantile R^2 connectedness (%) in a two-variable system of the Michigan one-year inflation expectation (FRED MICH, available monthly from January 1978) and month-on-month CPI inflation (CPIAUCSL), $n_{\text{lag}} = 2$ (a two-month lag horizon). NET is the net directional connectedness of expectations (TO – FROM); > 0 means expectations lead, < 0 that they follow. Because the monthly survey begins in 1978, the Great-Inflation sample covers only its final years (1978–82, 60 months) and should be read with caution. Dependence, not identified causation.

Table 14 Episode marginals for the inflation–expectations system (one-in/one-out)

Episode	Δ Overall	Δ Contemp.	Δ Lagged	Lagged %
$\tau = 0.7$				
Great Inflation (pre-1983 in)	+28.5	+4.8	+23.7	83.1
COVID (2020– in)	-0.1	-4.5	+4.4	-4533.3
$\tau = 0.9$				
Great Inflation (pre-1983 in)	+14.4	-0.8	+15.1	105.2
COVID (2020– in)	+12.2	+3.6	+8.7	70.8

Notes: One-in/one-out episode marginals for the quarterly two-variable system of Michigan inflation expectations (MICH_QTR) and quarter-on-quarter CPI inflation, constructed exactly as in Table 3: each row is total connectedness estimated with that episode included (and the other excluded) minus the calm 1983–2019 core, split into contemporaneous and lagged; $n_{\text{lag}} = 2$ (a six-month lag horizon). The pre-1983 sample runs from 1960, so the “Great Inflation” marginal includes the 1960s run-up. Dependence, not identified causation.

Fig. 1 Overall connectedness (black) and its decomposition into contemporaneous (blue) and lagged (red) components, by inflation quantile τ (monthly, $n_{\text{lag}} = 2$).
